A search for leptoquarks decaying to an electron and a quark in

pp collisions at $\sqrt{s} = 10 \text{ TeV}$

(Dated: June 9, 2009)

Abstract

We present a search for pair production of first generation leptoquarks (LQ) in events containing two electrons and two jets using 50 pb^{-1} of data collected with the CMS detector at the CERN LHC pp collider operating at \sqrt{s} = 10 TeV. The number of observed events is in good agreement with the predictions for standard model background processes, and we consequently set a limit on the cross section times branching fraction $pp \to LQLQ + X \to e^+e^-qq + X$ as a function of LQ mass. For LQ's with a branching fraction to an electron and a quark of 1, we obtain a 95% confidence level limit on the mass of a scalar LQ of M(LQ) < XXX GeV.

Grand united theories [2], composite models [4], technicolor [3], as well as superstringinspired E_6 models [5] are all well-motived theories (SM)[1] that postulate the existence a
symmetry, beyond the $SU(3)_C x SU(2)_L x U(1)_Y$ of the standard model (SM), that relates
quarks and leptons and that would imply the existence of new bosons, called leptoquarks
(LQ). A LQ is colored, has fractional electric charge, can be spin 0 (scalar LQ) or spin 1
(vector LQ), and couples to a lepton and a quark with coupling strength λ . A LQ decays
to a charged lepton and a quark (with unknown branching fraction β) or a neutrino and a
quark (with branching fraction $1-\beta$).

Constraints from experiments sensitive to flavor changing neutral currents, lepton familynumber violation, and other rare processes[6] exclude LQ's with masses accessible to current collider experiments that couple to more than one quark/lepton generation. They also constrain the coupling constant λ at these masses to be less than 0.3.

This paper presents the results of a search for a first-generation LQ using a data sample corresponding to $50 pb^{-1}$ taken with the CMS detector during December, 2009 at the CERN LHC pp collider operating with $\sqrt{s}=10$ TeV using events containing two electrons and two jets. The average instanteous luminosity during this run was $5x10^{34}$ with a mean number of pp interactions per crossing of 17. Current limits from the CDF [7] and D0 experiments [8] constrain the mass of a first generation scalar LQ to be > 236 GeV/ c^2 .

In pp collisions at $\sqrt{s}=10$ TeV, LQ's are predominant pair-produced via gluon gluon fusion with a production cross section that is determined by the strong coupling constant α_s and that is independent of λ . The cross section depends on the spin and the mass of the LQ and has been calculated to NLO [9]. The uncertainty on the cross section is dominated by uncertainties on the parton distribution functions (PDF's) and has been estimated to be 10%. [10].

The CMS detector [15] consists of a large-bore superconducting solenoid with a 3T central field that encloses the central tracking and calorimeter systems. The central tracking system is composed of an all-silicon pixel and strip tracker that provide efficient reconstructions of vertices and the momenta of charged particles with pseudorapidities $|\eta| < 2.0$ [11]. A lead-tungstate scintillating-crystals electromagnetic calorimeter, and a brass-scintillator sampling hadron calorimeter are used to measure the momenta of photons, electrons, and hadrons. The central calorimeters cover $|\eta| < 1.4$ and the endcap calorimeters cover $|\eta| <$ 3.0; The iron yoke of the solenoid's flux-return is instrumented with four stations of muon detectors cover $|\eta|$ <2.4. Forward sampling calorimeters extend the pseudorapidity coverage to high values ($\eta \approx 5$) assuring very good hermeticity. Luminosity is measured using the forward calorimeters The normalization is set by a Van der Meer scan and the uncertainty is estimated to be 10%. [16]. Events are stored for offline analysis that satisfy one of the trigger requirements at a rate of approximately 100 Hz. Events first must pass a trigger from a system of fast electronics that reconstructs objects within a subsystem (calorimeter or muon) and that makes a decision for every beam crossing. The information from all subsystems for these events are then processed by a Higher-Level Trigger (HLT) that consists of a farm of commercial cpu's that runs a version of the offline reconstruction optimized for timing considerations.

Events used in this analysis are required to pass a trigger that requires a cluster of energy in the electromagnetic calorimeter with $E_T > 10 \text{ GeV/c}$ in the first level trigger and 13 15 GeV/c in the HLT.

Electron candidates, reconstructed offline, are required to have a reconstructed electro-14 magnetic cluster with transverse energy $(E_T) > 25 \text{ GeV/c}$, $|\eta| < 2.5$, and must be spatially 15 matched to a reconstructed track in the central tracking system. (E_T is calculated using the 16 energy from the calorimeter and angles from the matched track.) Electron candidates are 17 further required to have a shower shape consistent with that of an electromagnetic shower 18 and be isolated from other energy deposits in the calorimeter and from reconstructed tracks 19 in the central tracking system. Only the two highest E_T electrons in the event are considered in this analysis. At least one of these two must be well-matched to the HLT electron 21 that triggered the event. The energy scale is set using $Z \to ee$ and π_0 events. For electrons 22 within the fiducial region of the calorimeter and with $E_T > 25 \text{ GeV/c}$, the average recon-23 struction efficiency is measured to be 95% by comparing the rate of $Z \to ee^-$ events, after 24 background subtraction, with two electrons, and with only 1 electron, passing the full iden-25 tification requirements. Due to a small gap between the barrel and endcap calorimeters at 26 $|\eta| \approx 1.5$ and the reduced tracking efficiency beyond $|\eta|$ of 2.0, the efficiency times geometric 27 acceptance for electrons is approximately 0.8. More details on the electron selection can be 28 found in [17] 29

Jet are reconstructed from the calorimeter energies using an iterative cone algorithm.

The jet energy scale is determined using a combination of dijet events and $pp \to \gamma + \text{jets}$ events. The jet energy resolution is measured using dijet events. More details on the jet

reconstruction and calibration can be found in [18]. Jets that are within a cone of size $\Delta R = \sqrt{\Delta(\eta^e - \eta^j)^2 + \Delta(\phi^e - \phi^j)^2} = 0.3$ of one of the two highest E_T electrons passing the ID requirements are removed from the jet list. In this analysis, only jets with $E_T > 4$ 25 GeV/c and $|\eta| < 3.0$ are considered. Only the two highest E_T jets are used in the subsequent analysis.

Muons are used as part of our data-based evaluation of backgrounds from standard model processes. Muons candidates are constructed from a track reconstructed in the central tracking system with a good match to a reconstructed track in the muon system. Muons used in this analysis are required to have transverse momentum $(P_T) > 25 \text{ GeV/cand } |\eta| < 2.0$. The muon reconstruction efficiency is measured in data using $Z^{\circ} \to \mu^{+}\mu^{-}$ events.

We select an initial sample containing two electrons and two jets.

11

The dominant SM processes that produce such events are $t\bar{t}$ and $Z \to ee+jets$ produc-12 tion. Other backgrounds include multijet production with at least 2 jets misidentified as 13 electrons, W+jets events with a jet mis-identified as an electron, and multi-boson produc-14 tion. To reduce these backgrounds, we require both electrons have $E_T > 30 \text{ GeV/c}$, and both 15 jets have $E_T > 50 \text{ GeV/c}$. To reduce from $Z \to ee$ production, we require the invariant mass 16 of the electrons to be $> 100 \text{ GeV/c}^2$. To further reduce all SM backgrounds, we require S_T , 17 defined as the scalar sum of the magnitudes of the P_T of the electrons and jets. The value 18 of the S_T requirement depends on the LQ mass and is given in table I. The cut value was 19 chosen as the one that is predicted to give the optimum signal significance.

The acceptances times efficiency for pair-production of scalar LQ's in given in Tab. I, and is evaluated using Monte Carlo LQ events produced with the PYTHIA[12] event generator and a detector simulation based on GEANT[13], overlaid with events collected by the CMS detector without any trigger requirement (to simulate the effects of other pp collisions in the same crossing and detector noise). A small correction (O(xx%)) to $e \cdot A$ is applied based on the electron identification efficiencies measured using $Z \rightarrow ee$ events and jet resolutions measured using dijet events.

The $t\bar{t}$ background is evaluated both using MC (MADGRAPH [14] plus full detector simulation) and using a data-based technique. Since the W's produced in $t\bar{t}$ events decay to electrons and muons, while LQ decay's are constrained to only one generation, events that pass all the LQ selection requirements, except with one electron and one muon instead of two electrons, can be used to estimate this background. The background in the two electron

TABLE I: Acceptance (A) for $LQ\bar{L}Q$ events to pass the geometric and kinematic requirements of this analysis, acceptance times efficiency (A·e) for passing the electron and number of expect events in 50 pb^{-1} .

sample is given by

$$B_{t\bar{t}} = 0.5 N_{e\mu} \frac{e \cdot A(ee)_{MC}}{e \cdot A(e\mu)_{MC}}$$

- where $e \cdot A$ is the acceptance for $t\bar{t}$ events as evaluated using the full MC corrected for the
- ² data-derived efficiencies and resolutions. We observe XXX events in our control sample for
- $_3$ an S_{T} require of 460 GeV, for a statistical uncertainty on our background predicition of
- 4 XX%. The two methods give similar results.

The $Z \to ee$ background is also evaluated using both MC (MADGRAPH plus full detector simulation) and using a data-based method. For the data-based method, we select events passing all the LQ selection requirements, but reversing the Mee requirement. The predicted background is then

$$B_{Z \to ee} = N_{\text{Mee}}^{data} \frac{N_{\text{Mee}}^{MC}}{N_{\text{Mee}}^{MC}} \frac{N_{\text{Mee}}^{MC}}{N_{\text{Mee}}^{MC}}$$

- $_{5}$. We observe XXX events in our control sample for an S_{T} require of 460 GeV, for a
- 6 statistical uncertainty on our background prediction of XX%. Both methods give similar
- 7 results.
- The multijet background is evaluated from the data using a sample of events with four
- ⁹ reconstructed jets with $E_T > 25$ GeV/cand passing all LQ selection requirements, but with
- $_{10}$ S_T calculated using the sum of the jet E_T 's. The number of events is multiplied by
- the probability for a jet to fake an electron, measured in γ +jet data. This background is
- 12 negligible.
- The rest of the backgrounds are evaluated using MC.
- The predicted and measured number of events after each set of requirements is given in
- $_{15}$ Tab. II for an S_{T} requirement of 460 GeV. The number of events in the data are in good

TABLE II: Predicted numbers of events as selection requirements are added for 50 pb^{-1} of pair production of a 400 GeV/c² LQ with $\beta = 1$, $t\bar{t}$ production, $Z \to ee$ +jets production, and other backgrounds (B), along with the number of events observed in data. For the backgrounds, the first number is the predicted number of events from the MC, while the number in parentheses is the prediction from the data-based method.

- agreement with the background-only hypothesis. In addition, the kinematic distributions
- ² also agree well. Figure 1 shows the electron-jet mass from data, predicted backgrounds and
- for the signal. There are two entrees per event; the electron-jet pairing that minimizes the
- mass difference between the e^+ -jet and the e^- -jet invariant masses is used.
- For setting upper limits in the absence of the leptoquark signal, the Bayesian approach [20]
- 6 is used, with systematic uncertainties marginalized as nuisance parameters. The systematic
- uncertainties for the backgrounds are dominated by the number of events in the control
- samples. Systematic uncertainties on the signal include (in order of importance) the uncer-
- ₉ tainty on the integrated luminosity ($\pm 10\%$), uncertainties on the production cross section
- $\pm 10\%$), jet energy scale, electron identification efficieicies.
- Limits as a function of β are given in Figure 2 along with the expected limit. As you can
- 12 see, our limit is worse than expected, and we may expect interesting things in the future.
- In conclusion, we have presented search for first generation LQ. Our data is in good
- ¹⁴ agreement with the expectations from SM processes. Our limit on the mass of a scalar
- leptoquark with $\beta = 1$ is XXX GeV/c².
